DSLab

1. Introduction

Autoregressive (AR) generative models achieve the best results in density estimation tasks involving high dimension data, such as images or audio. They pose density estimation as a sequence modeling task. This report will elaborate PixelCNN model - one of the most important model in AR models.

1.1. Autoregressive model

AR is a class of generative models with a tractable likelihood. The model fully factorizes the probability density function on a data point **x** over all its elements as:

$$p(\mathbf{x}) = \prod_{i=1}^D p(x_i|\mathbf{x}_{< i})$$

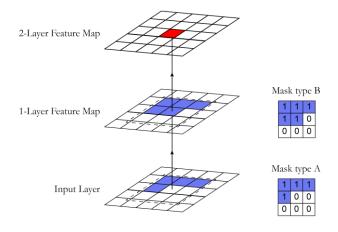

In the context of deep generative models, we will drop the condition of linear dependence and formulate our image problem as a random process. In particular, we will:

- Use a deep generative models (obviously non-linear), and
- Assume the pixels of an image are random variables with a specific ordering (top-down, bottom-up, left-right), which formulates it as a random process.

1.2. PixelCNN

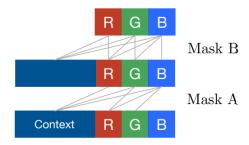

PixelCNNs are the convolutional version of PixelRNNs, which treat the pixels in an image as a sequence and predict each pixel after seeing the preceding pixels (defined as above and to the left, though this is arbitrary).

PixelRNNs are slow to train since the recurrence can't be parallelized — even small images have hundreds or thousands of pixels, which is a relatively long sequence for RNNs. Replacing the recurrence with masked convolutions, such that the convolution filter only sees pixels above and to the left, allows for faster training.

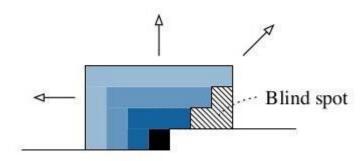

There are two types of mask. Mask type A does not consider the value of itself and are used in the first convolution layer. While mask type B consider the center element's value and are used in the following convolution layers.

When we experiment on color images, we need to consider the color conditioning on each pixel. We choose the sequent order is R -> G -> B. We also have two mask types. In mask type A, channels are not connected to themselves and only used in first convolution layer. And in mask type B, channels are connected to themselves and used in all subsequent convolution layers.

However, it's worth noting that the original PixelCNN produced worse results than the PixelRNN. One possible reason is that stacking masked convolutional filters results in blind spots, failing to capture all the pixels above the one being predicted

In order to increase the performance of pixelCNN, Gated PixelCNN was proposed to remove the blind spot by combining two convolution stack: one is horizontal stack and another is vertical stack.

Generating samples

Generating images is something that is a bit more complicated but follows the same idea from my post on Autoregressive Autoencoders:

- 1. Set i=0 to represent current iteration and pixel.
- 2. Start off with a tensor for your image x(0) with any initialization.
- 3. Feed x(i) into the PixelCNN network to generate distributional outputs y(i+1).
- 4. Randomly sample sub-pixel u(i+1) defined by y(i+1).
- 5. Set x(i+1) as x(i) but replacing the current sub-pixel with u(i+1).
- 6. Repeat step 3-5 until entire image is generated.

2. Experiments

2.1 Training details

n_filters: 64

Batch size 128

• Learning rate 0.001

Resnet block:

- ReLU
- 1x1 mask type B with in_channels = n_filters and out_channels = n_filters // 2
- ReLU
- 7x7 mask type B with in_channels = n_filters//2 and out_channels = n_filters//2, padding 3
- ReLU
- 1x1 mask type B with in_channels = n_filters//2 and out_channels = n_filters

Model:

- 7x7 mask type A with in_channels = input_channels, out_channels = n_filters, pading
 3
- (Layer normalizing + Resnet block) * num_resblock
- ReLU
- 1x1 mask type B with in_channels = n_filters and out_channels = n_filters
- ReLU
- 1x1 mask type B with in_channels = n_filters and out_channels = n_filters*n_colors

2.2 MNIST dataset

This dataset includes 60000 digit hand writing images from 0 to 9 in training set.

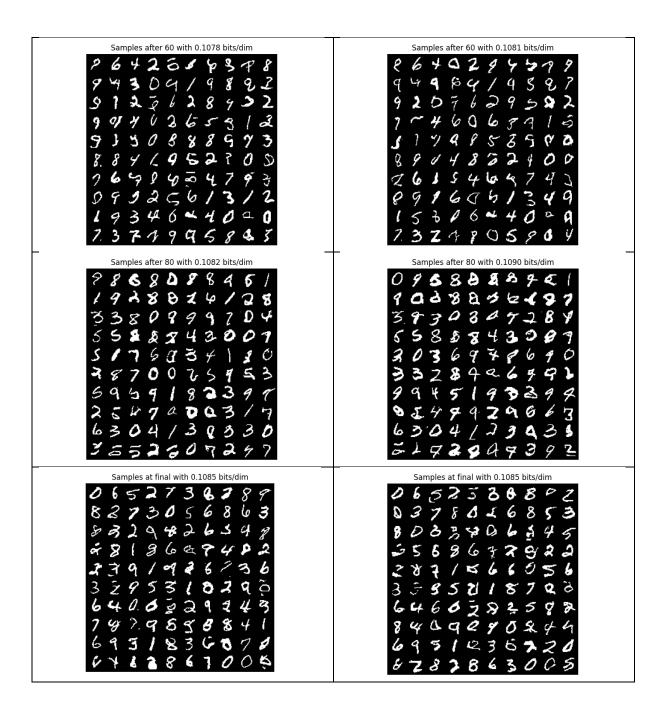

Each class has 6000 images with size 28x28

MNIST Samples 13250;6/82 4866940434 3533094492 1803353945 3923862948 4097028412 9868473104 1899999128 4137/37654

2.2.1. The effect of layer normalization

We training the above pixelCNN model with 100 epochs, skip connection and 5 resnet block

Layer normalization	No layer normalization
Samples after 0 with 0.1241 bits/dim 9	Samples after 0 with 0.1291 bits/dim 2.

The training curves

2.3. CELEB dataset

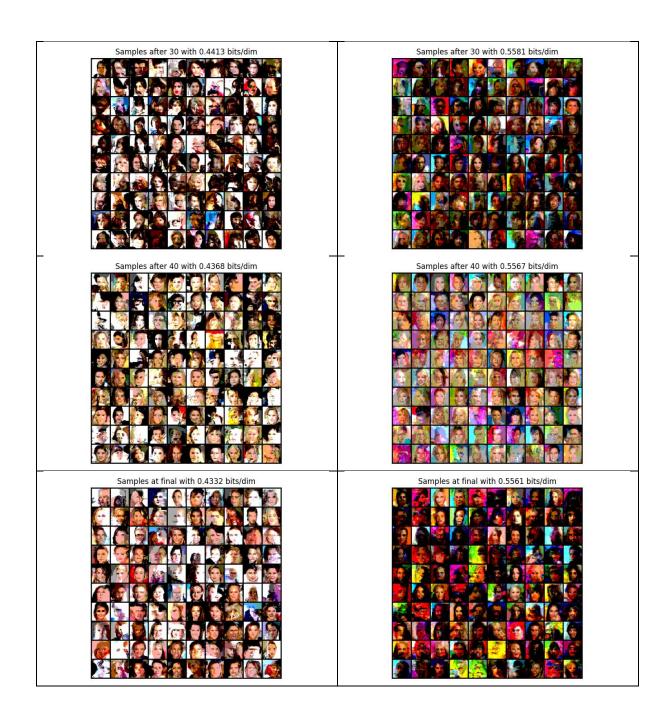

CelebFaces Attributes Dataset (CelebA) is a large-scale face attributes dataset with more than 200K celebrity images.

2.3.1. The effect of color conditioning

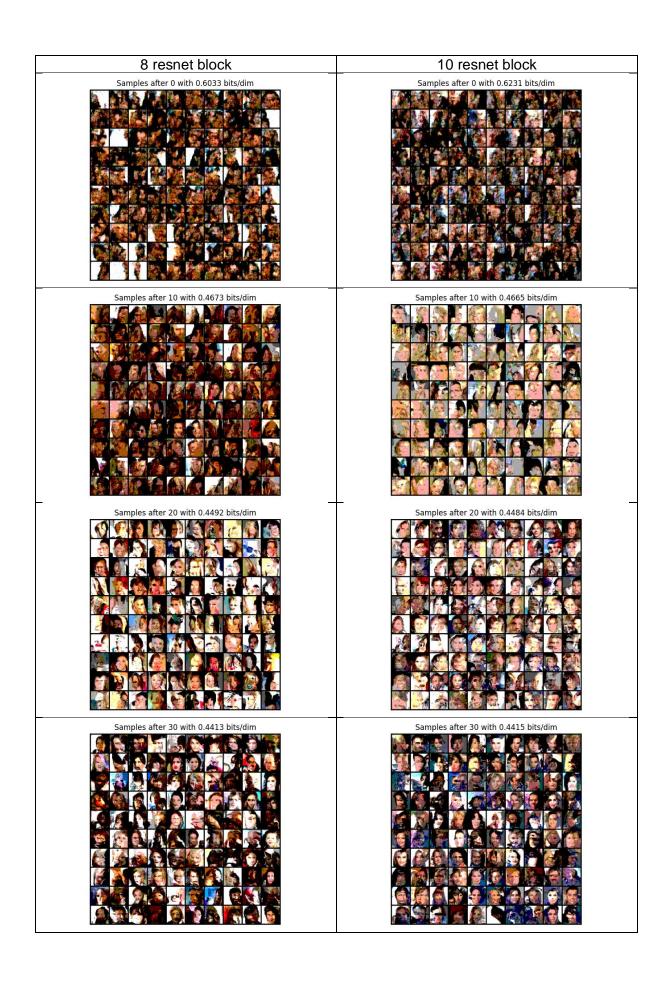

We training our models with 50 epochs and using layer normalizing with skip connectiong

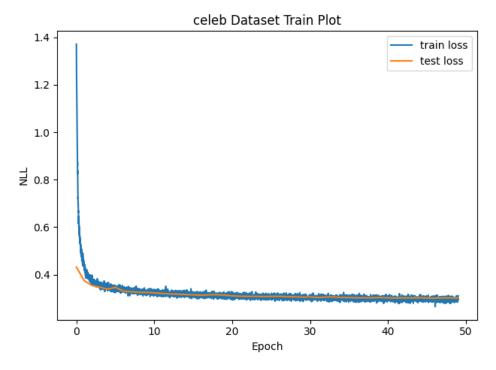

2.3.2. The effect of the number of resnet block

Using layer normalizing, 50 epochs and color conditioning with skip connection.

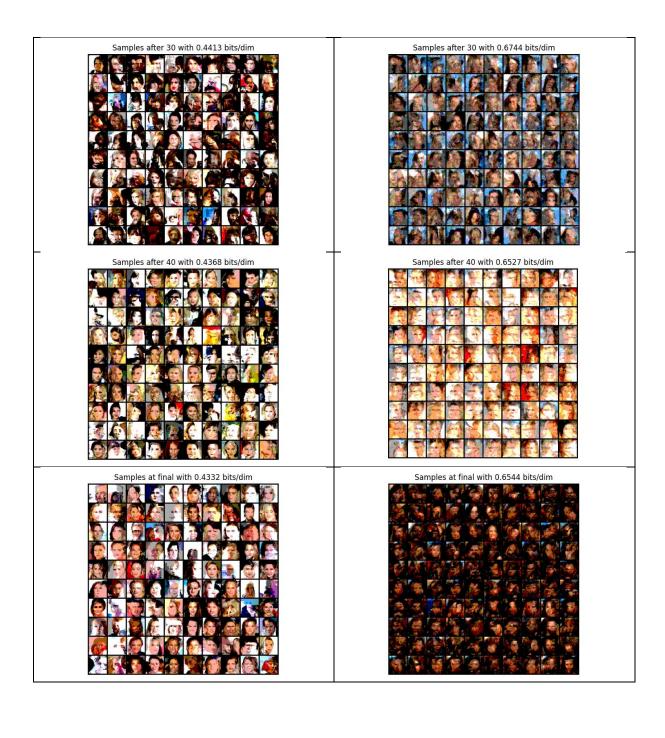

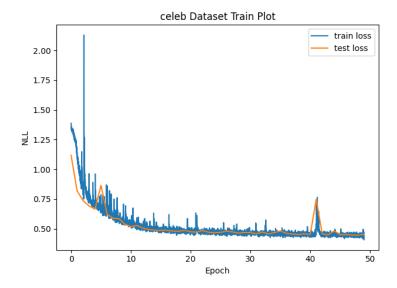

Training curve of training with 10 resnet blocks

2.3.3. The effect of skip connection

Using layer normalizing, 50 epochs and color conditioning with 8 resnet block.

Skipped	No skipped
Samples after 0 with 0.6033 bits/dim	Samples after 0 with 1.6137 bits/dim
Samples after 10 with 0.4673 bits/dim	Samples after 10 with 0.7486 bits/dim
Samples after 20 with 0.4492 bits/dim	Samples after 20 with 0.6843 bits/dim

Training curve of training without skip connection

3. Conclusion

In this report, we reviewed the concept of Autoregressive models. Besides, we elaborated the pixelCNN model to know how it works and how it generates samples. Throughout experiments, we can see that pixelCNN can generate MNIST images slightly realistic. But with Celeb dataset, the generated images are still bad and not clear. We will try some advanced methods such as Gated PixelCNN, PixelCNN++ and PixelSnail to improve the quality of generated images as soon as possible.
